INTRODUCTION

The increasing emphasis on the promotion of health has led to a growing interest in utilizing models based at early disease prevention. It is of unanimous knowledge that the etiology of dental caries is multifactorial, and that will not occur without the presence of the microorganism. The cariogenic bacteria Mutans Streptococcus (MS) plays a major role in the course of this disease. Thus, the suppression and stabilization of MS to non-pathogenic levels for longer periods is of vital importance in the prevention of dental caries. Nevertheless, it seems to be difficult to decrease MS in caries-active patients. For this purpose, several antimicrobial agents have been introduced in preventive regimens. Chlorhexidine (CHX) has been proved to be the most potent chemotherapeutic agent against MS and dental caries. A number of studies have used a variety of methods for delivering chlorhexidine in mouthrinses, gels, or dentifrices for caries prevention.

In 1985, Balanyk and Sandham developed a CHX-containing antibacterial varnish that brought a new concept into preventive dentistry. This vehicle was safe in humans, compatible with CHX and able to release the chemotherapeutic agent into the oral environment at low but bactericidal levels for approximately two weeks. This sustained release CHX varnish was proven to be successful at suppressing MS for prolonged periods and more effective than other CHX vehicles. In addition to the property of slow-release, the enhanced suppressive effect of varnish on the MS colonization is likely due to the prolonged contact time between CHX and teeth.

According to Shaeken et al.11, the anticaries effect of the CHX varnishes is believed to consist of the reduced cariogenicity of dental biofilm after the suppression of MS, due to the high sensitivity of this microorganism to the CHX.

Several studies have reported that the application of a CHX varnish was successful in reducing oral MS5,10,12–14 and caries increment. With a number of long-term controlled clinical trials being performed all around the world, CHX varnishes may soon be highly considered in combination with already established preventive methods against the development of dental caries.
Chlorhexidine varnishes in children

Based on the existing literature, the purpose of this paper is to review current information regarding the utilization of three different CHX varnishes that are available in the world’s market today and to illustrate the step-by-step procedure for its use in children.

LITERATURE REVIEW

Efficacy in MS reduction/ Antimicrobial activity

Numerous studies demonstrate the effect of CHX varnishes in the suppression of MS in saliva and dental biofilm\(^9,10,12-14,17\). Nevertheless, the extent of this suppression depends on the concentration and frequency of exposure to CHX\(^12\). Several authors reported that after use of CHX in the form of varnish, bacterial growth can be supported for three months or more\(^9,18\).

Schaeken et al.\(^18\) tested the effect of several CHX concentrations (0%, 10%, 20%, 40%) within the varnish and concluded that the optimal concentration for this varnish was approximately 40%. In 1989, Schaeken and de Haan\(^18\) treated twelve subjects with a 50% CHX varnish once or twice within one week and a significant suppression of MS was found in the interdental biofilm until the fourth week. In addition, the saliva samples showed MS suppression for the entire experimental period approximately 6 weeks. On the other hand, Schaeken et al.\(^9\) proved that a single application of a 40% CHX varnish with a reduced contact time of 15 minutes was sufficient to achieve a long-term suppression of MS levels in interproximal dental biofilm until 16 weeks. Ie and Schaeken\(^12\) analyzed the effects of one or two applications of 40% of CHX varnish on the numbers of MS in human dental fissure biofilm from molar and premolar teeth. According to their findings, a stronger suppression of MS can be obtained after repeated treatment with 40% CHX varnish, particularly for premolars.

Placement of fixed orthodontic appliances is normally followed by an increase in oral colonization by MS concomitant with an elevated risk for the development of dental caries\(^15\). Eronat and Alpöz\(^20\) evaluated the efficiency of a 1% chlorhexidine-containing varnish on the levels of MS in saliva of patients with fixed orthodontic appliance. The results from their study suggested that 1% CHX varnish reduced salivary MS levels for 1-month period and that the application should be repeated every 3 months to get antibacterial effect. Sandham et al.\(^21\) also indicated that CHX varnish was also effective in suppressing MS levels for long periods in child orthodontic patients, with a significant reduction of MS counts until three months of post-treatment.

From a brief microbiologic perspective, after intensive treatment, CHX varnish kills all bacteria on the treated surface of the teeth. After a few hours, the surface of teeth will be recolonized by a range of bacteria which adhere from the saliva and start to multiply. Species of bacteria that are less sensitive to CHX, such as oralis streptococci, have the best chance to multiply. In contrast, within the streptococci group, the MS are the most sensitive to CHX. Therefore, CHX varnish causes a shift in the oral microflora and, consequently, the selective suppression of MS. Other species takes the place of MS in the ecosystem, thus long-term reduction in the counts of MS in biofilm leads to a noticeable reduction in caries incidence\(^11\).

Caries prevention

Joharji and Adenubi\(^22\) evaluated the prevention of pit and fissure caries using a 1% CHX varnish during a period of nine months. Their results concluded that the application of the antimicrobial varnish on occlusal surfaces of permanent molars significantly reduced the development of fissure caries. Similar findings were confirmed by Bratthall et al.\(^15\) and Araujo et al.\(^16\) showing that occlusal fissures of permanent molars treated with CHX varnish developed significantly less carious lesions in a two-year period.

Recently, Baca et al.\(^23\) demonstrated that schoolchildren in three-monthly applications of 1% CHX varnish with no decayed or filled primary teeth at baseline showed a significantly lower incidence of caries lesions in primary molars (at 24 months) compared with a control group.

On the other hand, a study performed using 40% CHX varnish in a population with low caries prevalence demonstrated no caries-reducing effect on occlusal surfaces in recently erupted permanent molars\(^24\). Furthermore, Twetman\(^25\) in a review of the effect of the antibacterial methods concluded that the use of CHX varnishes for the prevention of caries in high-risk subjects has inconclusive evidence. This author
suggested that the antibacterial treatments should always be accompanied by other preventive measures in caries-active children.

**The utilization of CHX varnish in Early Childhood Caries (ECC)**

ECC is a particularly virulent form of dental caries characterized by an overwhelming infectious challenge, with MS being the most likely causative agent. This bacterial accumulation is most often associated with inappropriate bottle habit or nocturnal bottle and breast-feeding practices, which plays a critical role in the early acquisition and clinical expression of this infection. Furthermore, deleterious feedings practices in conjunction with inadequate oral hygiene practices have also been described as responsible for MS proliferation. According to Berkowitz, the elevated levels of MS in ECC children regularly exceeded 30% of the cultivable biofilm.

Treatment of ECC is generally restricted to early extraction of teeth and comprehensive restorative procedures with recommendations regarding improvement of dietary and feeding habits. However, restorative dentistry has little impact on oral levels of MS. In addition, apparently, the available fluoride therapies do not give sufficient protection to high active-caries individuals, such as those diagnosed with ECC. Since there is considerable evidence that children who experience ECC continue to be at high risk for new lesions in later years, it seems reasonable that additional antimicrobial therapies are necessary to modify the course of the disease and to prevent the future development of carious lesions in children who experienced ECC.

There is one study in the literature that demonstrated the efficacy of CHX varnish in the prevention of the ECC. According to their results, the DMFS scores were significantly lower in a group of children that were treated with 3-monthly applications of CHX varnish when compared to a control group. However, there are no studies in the literature using CHX varnish in youngsters being treated for ECC and highly susceptible to new carious lesions.

The use of CHX varnish is suitable and safe for very young child. The amount used is smaller than that for use of gel or mouthrinses and also does not rely on patient compliance. It also should be stressed that CHX varnishes are of significant benefit, because reduce costs and causes less trauma to the young child by early prevention of dental caries.

**Types of CHX varnish**

For antimicrobial therapy against MS, treatments for professional and for home use are available commercially. Three types of CHX varnishes are available in the market:

**1. Cervitec** (Ivoclar/Vivadent AG, Schaan, Liechtenstein) (Figure 1) is a 1% CHX and 1% thymol formulation in a viscous polyvinyl butyral base, in addition to < 41% ethanol and < 50% ethyl acetate contents. Each milliliter of varnish contains 10 mg of CHX. Cervitec® is marketed by Ivoclar/Vivadent and it is supplied in a box containing 7 bottles, which includes a supply of 50 applicators "Vivabrushes" and 2 handles. Each bottle contains 1.5 ml of the varnish.

![Figure 1. Cervitec® (Ivoclar/Vivadent AG, Schaan, Liechtenstein).](image)

**2. EC40** (Biodent BV, Nijmegen, The Netherlands) (Figure 2) is a highly supersaturated solution of CHX diacetate in alcohol which is stabilized by sandarac, a naturally occurring resin. The concentration of CHX diacetate in EC40® is 35%, in addition to 27% sandarac and 37% ethanol. EC40® is supplied in a box with 10 cartridges. Each EC40® cartridge contains 1.5 ml of varnish.

**BioC** (Biodent BV, Nijmegen, The Netherlands) (Figure 3) is a solution of CHX diacetate in alcohol. The solution is too stabilized by sandarac that also has an antimicrobial potential. The percentage composition of CHX diacetate in BioC® is 20%, in addition to 37% sandarac and 43%
Chlorhexidine varnishes in children

ethanol. BioC® is delivered in handy plastic syringes. The box containing 4 syringes of 1.2 ml.

Figure 3. BioC® (Biodent BV, Nijmegen, The Netherlands).

Frequency of CHX varnish application

Caries risk assessment is a critical step in the frequency of CHX varnish application. According to Messer32, numerous factors must be identified for the appropriate classification of children into risk groups such as "high", "moderate", and "low" caries risk. In high risk children, the CHX varnish application should be more frequent than those with moderate or low caries risk. However, there is no protocol of frequency application in the reviewed literature. Fennis-Ie et al.24 analyzed a group of children who received treatment with EC40® in addition to the standard treatment, which also included a chlorhexidine application every six months. After a period of three years, it was found that EC40® had a 35% caries reduction in addition to that achieved by six-monthly chlorhexidine applications alone. Moreover, Twetman and Peterson33 evaluated proximal caries incidence and progression in schoolchildren at high risk. Cervitec® was applied three times within a two-week period. The results of their study showed an appreciable reduction in caries incidence and progression. In a prospective clinical trial carried out by Galganny-Almeida et al. (2004) with Brazilian children diagnosed with ECC, three-monthly Cervitec® varnish applications demonstrated a 43% reduction in caries in the varnish group when compared to a group receiving three-monthly fluoride applications alone34.

Step-by-step CHX varnish application procedure

The most important aspects of treatment with CHX varnish are summarized in Table 1. The varnishes must be applied by a dentist or dental hygienist.

<table>
<thead>
<tr>
<th>Table 1. Recommended treatment regimen by manufacturer</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Cervitec®</strong></td>
</tr>
<tr>
<td>• Clean tooth surfaces thoroughly (prophylaxis with gauze, toothbrush or professional);</td>
</tr>
<tr>
<td>• Dry with cotton rolls and air syringe, however area does not have to be completely dry;</td>
</tr>
<tr>
<td>• Apply a thin coat of varnish by means of a suitable brush; in proximal surfaces with closed contact, the varnish is best applied with dental floss (Figure 3);</td>
</tr>
<tr>
<td>• Remove cotton rolls after 30 seconds;</td>
</tr>
<tr>
<td>• Do not ask the patient to rinse the mouth;</td>
</tr>
<tr>
<td>• Recommendations. After the application of the varnish (Figure 4), patients should be asked to refrain from eating and drinking for 3 hours, toothbrushing for 24 hours and flossing in treated areas for 3 days.</td>
</tr>
<tr>
<td><strong>EC40®</strong></td>
</tr>
<tr>
<td>• The dentition is cleaned; in principle plaque does not have to be removed;</td>
</tr>
<tr>
<td>• Apply a thin layer of varnish using a carpule syringe; this prevents excess varnish;</td>
</tr>
<tr>
<td>• Treat the location for which caries has a predilection. It is not necessary to treat all surfaces;</td>
</tr>
<tr>
<td>• The varnish can be left in place after application or can be removed after 10-15 minutes. The patient can also brush off the varnish at home.</td>
</tr>
</tbody>
</table>

**Indications**

1. Reduce bacterial activity35.
2. Inhibit demineralization of tooth structure36.
3. Protection of enamel and dentin (Protection of exposed root surfaces and treatment in the hypersensitivity of the cervical areas of tooth structure)36.
Advantages
1. Ease of application\textsuperscript{22}.
2. Patient compliance is assured\textsuperscript{3, 8, 29}.
3. Children readily accept CHX varnishes\textsuperscript{21, 22}.
4. CHX varnishes are highly concentrated in their active content, therefore small amounts of CHX varnish when professionally applied to the teeth is sufficient to reduce high titers of MS for long periods\textsuperscript{18}.
5. The cumulative dose of CHX in the varnish is lower than repeated rinsing with CHX mouthrinse. As a result, the common side effects of tooth staining and loss of taste can be avoided\textsuperscript{14}.
6. The local irritation of the oral mucosa is common in the frequent use of CHX; however avoidance of the varnish application to the soft tissue minimizes irritation to the oral mucosa\textsuperscript{18}.

Disadvantages
1. The cost for CHX varnish is increased compared with other types of CHX delivery systems.
2. Bitter taste\textsuperscript{9}.
3. Some aesthetical discomfort, when anterior teeth are treated with varnish due to temporary peeling of the varnish\textsuperscript{9}.

Toxicity and Ingestion

To date there are no reports of serious side effects with the use of CHX varnish\textsuperscript{3}. The reduction of these side effects could be most probably attributed to the low frequency of application of the CHX varnish when compared to other methods such as mouthrinses and gels\textsuperscript{14}. Moreover, the possibility for ingestion of the CHX is significantly reduced when used in the form of the varnish\textsuperscript{14}. In individual cases, contact with the mucous membrane may result in short-term, reversible irritation\textsuperscript{11}. Though CHX in the form of mouthrinses and gels causes reversible discoloration of the tooth structure\textsuperscript{37}, the varnish itself acts as a protective layer to prevent the teeth from staining\textsuperscript{7}. Moreover, soreness of the oral mucosa by the use of CHX mouthrinses can be overcome by the use of local varnish application\textsuperscript{37}. Desquamation with the use of the varnish are rare, because both frequency of use and concentration of CHX reaching the oral tissues are very low\textsuperscript{7}.

CONCLUSION

A safe application of high concentrations of CHX in children is possible when its use is in the form of varnishes. Moreover, the CHX remains in the oral cavity over extended periods of time, thus the suppression and stabilization of MS to non-pathogenic levels are clearly observed overtime. The high incidence of caries in children following comprehensive restorative treatment for Early Childhood Caries is being highly reported, so antimicrobial therapy with the use of CHX varnish may be very beneficial for this group of children. In addition, the application of CHX varnish in child orthodontic patients can also be useful for the prevention of dental diseases. This study suggests that more research is urgently needed to determine the optimal preventive regimens, including antimicrobial therapies to prevent and modify the course of oral diseases in children.
